

FISHING INDUSTRY RESEARCH TRUST ACCOUNT

PROJECT 84/27: Identification of deep-water trawl fish stocks using parasites as markers. University of Queensland and Department of Sea Fisheries, Tasmania

FINAL REPORT, PART I. ORANGE ROUGHY

Orange roughy are a relatively sedentary species with little movement between fish management zones. This is the conclusion of our analysis of the numbers of parasites in the gut wall of 1251 orange roughy Hoplostethus atlanticus from eight areas off southern Australia and three areas off New Zealand (Fig. 1).

Fish from each area were divided into three length groups which averaged close to 28, 37 and 42 cm. Statistical analysis of data on larval nematodes (Anisakis spp., Terranova sp., and a spirurid) and larval cestodes (Hepatoxylon trichiuri and Callitetrarhynchus sp.) discriminated five Australian and three New Zealand stocks. These were: Great Australian Bight (area 1); South Australia/west Victoria/west and south Tasmania (areas 2,3,4 and 5); Cascade Plateau/Tasman Rise (area 6); north-east Tasmania (area 7); New South Wales (area 8); north-east New Zealand (9); south-east New Zealand (10); and west New Zealand (11) (Figs 2 and 3).

In four pairs of samples, little difference was found between the parasite fauna of fish taken during the spawning season and those taken outside the spawning season in the same area. Along the west coast of Tasmania there was a gradual increase in the numbers of larval ascaridoid nematodes as one moved south. This was apparent in both small (immature) and medium-sized (mature) fish. These results suggest that at least

medium-sized fish spawn in the same locality that they inhabited as juveniles.

Two manuscripts have been submitted for publication:

- 1) Lester, R.J.G., K.B. Sewell, A. Barnes and K. Evans. Stock discrimination of orange roughy Hoplostethus atlanticus by parasite analysis. Submitted to 'Marine Biology'.
- 2) Sewell, K.B. and R.J.G. Lester. The numbers of selected parasites in Australian and New Zealand samples of orange roughy Hoplostethus atlanticus, 1983 to 1986. Submitted to 'Tasmanian Fisheries Research'.

Copies of the manuscripts have been lodged with FIRTA.

FIGURE CAPTIONS

Figure 1. Origins of the eleven samples of orange roughy from Australia and New Zealand, and the 1000m depth contour.

Figure 2. Graphical representation of the similarities of the parasite faunas of large roughy from Australian samples. The first two canonical axes from a multivariate analysis are shown. Each sample is represented by a point surrounded by a circle indicating the 99% confidence limit. Note that the parasite faunas of areas 1 and 6 are distinct from other areas. When the third axis was taken into account, area 7 was separated from all other areas at the 95% level of confidence.

From 1983 to 1986, 40 samples of orange roughy from Australia and New Zealand were dissected and the numbers of selected parasite species recorded. Most of the data was used for the analysis in Lester, Sewell, Barnes and Evans (in press).

This paper contains the raw data. Australian fish are listed first (Tables 1 to 3) followed by New Zealand fish (Tables 4 to 6). The length of Australian fish was recorded as length to caudal fork (LCF). The length of New Zealand fish was recorded as standard length (SL) and converted to LCF by the formula, $LCF = (SL \times 1.10) + 0.195$ (New Zealand Ministry of Agriculture and Fisheries, personal communication). For each country, data from small fish (20 to 34 cm LCF) are followed by those for medium sized fish (35 to 39 cm LCF) and for large fish (40 to 48 cm LCF). At the end of each table there is a group of fish separated by a blank line. These are the short and long fish removed from each size group to equalize the mean length prior to the analysis in Lester et. al. Asterisks indicate unknown data.

The 22 columns in Tables 1 to 6 refer to the following:

Column

1	Autopsy number
2	Area (see Figure 1)
3	Area sample number
4	Capture date (day month year)
5	Fish length (LCF cms)
6	<u>Sphaeromyxa</u> sp. (1 = present, 0 = absent)
7	Spirurid sp.
8	<u>Hepatoxylon trichiuri</u>
9	Degenerate <u>H. trichiuri</u>
10	<u>Tentacularia</u> sp.

11	<u>Sphyriocephalus</u> sp.
12	<u>Callitetrarhynchus</u> sp.
13	<u>Anisakis</u> type 1
14	<u>Anisakis</u> type 2
15	<u>Anisakis</u> type 3
16	Degenerate <u>Anisakis</u>
17	<u>Terranova</u> sp.
18	<u>Echinorhynchus</u> sp.
19	<u>Ascarophis</u> sp.
20	<u>Glomericirrus</u> <u>amadai</u>
21	<u>Pseudopecoelus</u> sp.
22	Scolex polymorphus

Tables 1 to 6 are followed by Table 7 which gives the locations for the 40 sampling sites and other details.

Representative specimens for the 14 parasite species have been lodged in the Queensland Museum. Their accession numbers are listed in Table 8.

Abstract

The parasite fauna of the viscera of 1251 orange roughy Hoplostethus atlanticus from eight areas off southern Australia and three areas off New Zealand was examined for evidence of discrete host populations. Fish from each area were divided into three length groups which averaged close to 28, 37 and 42 cm. Canonical multivariate analysis of data on larval nematodes (Anisakis spp., Terranova sp., and a spirurid) and larval cestodes (Hepatoxylon trichiuri and Callitetrarhynchus sp.) discriminated five Australian and three New Zealand stocks. These were: Great Australian Bight; South Australia/west Victoria/west and south Tasmania; Cascade Plateau/Tasman Rise; north-east Tasmania; New South Wales; north-east New Zealand; south-east New Zealand; and west New Zealand. No significant differences in parasite fauna were detected between samples of fish taken within the spawning season and those taken outside the spawning season in the same area. In one southern Australian stock there was a north-south cline in the numbers of Anisakis spp. This was apparent in both small (immature) and medium-sized (mature) fish. We conclude that H. atlanticus is a sedentary species with little movement between fish management zones.

Introduction

Orange roughy Hoplostethus atlanticus is the basis of an established trawl fishery in New Zealand (Robertson, Grimes and

McMillan, 1982) and an emerging deep water trawl fishery in Australia (Wilson, 1982). The fish occurs in 900 to 1200 metres. A feasible means to tag it has not yet been developed.

The New Zealand fishery is based on aggregations thought to be associated with spawning. Robertson et al. (1982) suggested that between spawnings, fish were dispersed over several management areas, and that fish on the west of New Zealand probably constituted a single spawning stock. Isoenzyme studies on New Zealand and Atlantic fish showed that the species had high heterozygosity (Smith, 1986). Smith suggested that the species was widely distributed in the world at the 1000 metre isobar and the genetic similarity between the New Zealand and North Atlantic fish could be maintained by gene flow along the slope edge and gene-hopping between ocean ridges and sea mounts. He was unable to distinguish any stocks around New Zealand.

The use of parasites for separating marine stocks is a well established technique (Sindermann, 1983; MacKenzie, 1983,1987). Parasites, particularly larval stages, survive for extended periods in fish and some persist until the fish dies. As parasite species are rarely distributed uniformly over the host range, juveniles in one area will acquire a parasite species but not those in another. Thus the parasite fauna of adult fish reflects the environment in which it has grown. Margolis (1965) separated sockeye salmon in the north Pacific Ocean into those of North American or Asian origin using parasites acquired during the fishes' juvenile freshwater phase. In 1939 Dogiel and Bykhovski distinguished two stocks of sturgeon in the Caspian Sea using parasites common in the northern less saline waters but

largely absent from the south (Dogiel, 1961).

We used the natural parasite fauna of orange roughy to determine if there were consistent differences between fish from different geographical areas around Australia and New Zealand.

Materials and methods

Orange roughy were collected from 11 areas off southern Australia and eastern and western New Zealand (Fig. 1); these were: Great Australian Bight (area 1), South Australia (area 2), west Tasmania (areas 3 to 5), Cascade Plateau and Tasman Rise (area 6), east Tasmania (area 7), New South Wales (area 8), Challenger Plateau (area 9), combined Cook and Moeraki Canyons (area 10), and the Chatham Rise (area 11). Of the 1422 fish examined, 874 were provided by the Tasmanian Department of Sea Fisheries, 74 by the New South Wales Department of Agriculture Fisheries Division, and 474 by the New Zealand MAF Fisheries Research Centre. Fish were either gutted at sea or held in chilled brine for a maximum of 3 days and gutted immediately on landing. The viscera were stored frozen after being placed in a plastic bag with a label giving the fish caudal fork length (LCF), cruise number and haul number. They were later thawed and separated into their component parts for parasitological examination.

Parasites (Table 1) were recorded using the following methods. Prevalence of Sphaeromyxa sp. was assessed by searching for spores in gall bladder fluid using a compound microscope (x40 objective) for a maximum of five minutes. Trypanorhynch larvae (Hepatoxylon trichiuri, Callitetrarhynchus sp., Sphyricephalus sp. and Tentacularia sp.), the larval anisakid nematodes

(Anisakis spp. and Terranova sp.) and an unidentified species of larval spirurid were found in the mesentery and gut wall using the naked eye and a dissecting microscope with transmitted light. Digenea (Glomericirrus amadai and Pseudopecoelus sp.), Acanthocephala (Echinorhynchus sp.), tetraphyllidean larvae (Scolex polymorphus) and the nematode Ascarophis sp. found in the washings from the lumen of the stomach and intestine using a dissecting microscope. Representative specimens of these parasites have been lodged in the Queensland Museum; for accession numbers and a listing of the raw data see Sewell and Lester (in press).

The data were analysed in three ways: summary statistics, investigation into the similarities and dissimilarities of the parasite fauna between areas, and investigation of seasonal differences in average parasite numbers between areas.

Fish from each sample were divided into three size groups, small (20 to 34 cm LCF), medium (35 to 39 cm LCF) and large (40 to 48 cm LCF). Short or long fish were removed from each size group until the average length of each group was approximately 28, 37 and 42 cm LCF respectively, except for New Zealand samples where the average length of the small category was 29.8 cm LCF. Of the total number of fish dissected (1422), 1251 were used in the analyses. For each size group, the similarities and dissimilarities between areas were examined using canonical multivariate analysis (Mardia et al. 1979). The method was essentially as described by Lester, Barnes and Habib (1985) for their analysis of data from skipjack tuna. A single transformation of the natural logarithm of the number of

parasites plus one, was used on all parasite numbers. To further remove bias due to associations between parasite numbers and fish length, within each fish size group, transformed counts were adjusted for fish length. For each parasite species, a regression of transformed parasite number on fish length was undertaken, and the resulting relationship used to adjust the parasite numbers to that expected for a fish of 28, 37 or 42 cm LCF. No adjustment was made if the parasite number was zero.

A random number between -0.05 and $+0.05$ was added to all parasite data. This allowed matrix inversion in the canonical variate analysis which was otherwise impossible as some parasites were absent from some samples. The small addition did not significantly affect the outcome. The results of the canonical analyses were displayed as plots of the first, second and third canonical axes. Confidence limits (99%) for the points are presented as circles with radius equal to the square root of, 9.21 divided by the number of fish in the sample. Confidence limits at 95% were visualised as circles with radius equal to the square root of 5.99/number of fish in sample (Mardia et al. 1979).

The differences in average log (parasite number +1) between fish taken during the spawning season and those taken from the same site outside the spawning season, were investigated on 4 separate pairs of samples by an analysis of that variance which remained after each of a series of 5 models were fitted to the data. Model 1 was the total variability about the mean in the 237 fish tested. Unexplained variability was progressively reduced by successive models as follows: model 2 removed simple linear length effects; model 3, average differences between

sites; model 4, common seasonal differences between sites; and model 5, seasonal differences between sites. Using hierarchical and other analyses of variance constructed from the results of these models, it was possible to determine whether evidence existed for the presence of seasonal differences, either as common differences over all sites or as differences at particular sites.

Results

The 17 categories of parasites recognized (Table 1) were first evaluated for their probable longevity in fish and hence their reliability as host population markers. Intestinal helminths (No.s 13 to 17) were considered likely to be unreliable as their number could be affected by changes in diet (Lester et al., 1985). Some of these, such as the digenean Pseudopecoelus sp. (No. 11), the acanthocephalan Echinorhynchus sp. (No. 13), and the ascarophid (No. 14) showed negative correlations with host length (last column, Table 1) which suggested that they were parasites of juvenile fish which were lost as the fish grew. The prevalence of the gall bladder parasite Sphaeromyxa sp. (No. 1), also decreased as host length increased, suggesting a short-lived infection. The larval cestode Sphyriocephalus sp. (No. 6) encapsulated in the wall of the gut was too rare to be useful. Cysts containing Tentacularia sp. (No. 5) were common in the stomach serosa but many of them were degenerating. This and their small size made identification difficult and time consuming; they were not counted after 165 fish.

Parasites counted in all fish and used in the analyses were:

an unidentified larval spirurid (No. 2); the larval cestodes Hepatoxylon trichiuri (No.s 3 and 4) and Callitetrarhynchus sp. (No. 7); and the larval anisakid nematodes Anisakis type 1, Anisakis type 2, Anisakis 3, degenerate Anisakis spp. and Terranova sp. (No.s 8 to 12).

The spirurid (No. 2) was embedded in small brown cysts ϕ.5 mm. diameter in the wall of the stomach. Hepatoxylon trichiuri was encapsulated in the mesentery. It was identified from its large size, globular shaped tentacles and solid hooks the largest of which were longer than 180 um. Though it was uncommon, it was used because both live and dead worms were readily detected as a result of their large size and persistent hooks. Data on live (No. 3) and degenerate (No. 4) worms were combined for the analyses. Anisakis type 1 (No. 8) had a relatively long ventriculus with an oblique ventriculo-intestinal junction and a rounded mucron-bearing tail. Anisakis type 2 (No. 9) had a short ventriculus, a horizontal ventriculo-intestinal junction and a pointed tail with no mucron. Anisakis type 3 (No. 10) was a stout worm with a short ventriculus, a horizontal ventriculo-intestinal junction and a short mucron. Live and dead Anisakis were common in the mesentery and encysted in the wall of the gut, especially the stomach. Terranova sp. (No. 12) was a much smaller worm than any of the Anisakis species, had a prominent intestinal caecum and was usually found encapsulated in the stomach wall and occasionally the mesentery.

The nine parasite categories used in the analysis (No.s 2 to 4 and 7 to 12) showed positive correlations with host length (Table 1) suggesting they accumulated as the fish aged. This and the observations of other workers on closely related parasites

(MacKenzie, 1982) suggested that they may be reliable host markers.

Multivariate analyses of these data showed that for the small Australian fish the parasite fauna in NSW (area 8) was distinct from other Australian areas, most of which were clumped together (Fig. 2). In this analysis, the first two canonical axes accounted for 86% of the total variability. The third canonical axis, not shown, accounted for a further 6% and pulled 4 and 5 to one side but did not separate them from the main group at the 95% level of confidence. The parasite with the greatest discriminating power was Terranova sp.

Analysis of data from the medium and large Australian fish showed greater discrimination of areas (Figs. 3 and 4). For the medium fish, the first two canonical axes accounted for 80% of the total variation and again separated area 8, NSW, from the others (Fig. 3). The Great Australian Bight (area 1) and the Cascade Plateau/Tasman Rise (area 6) were pulled aside and separated by these axes at the 95% level of confidence but not at the 99% level. The third canonical axis, not shown, accounted for a further 13% of the variation and separated north eastern Tasmania (area 7) from the other areas at the 99% level of confidence.

For the large fish, the first two canonical axes accounted for 86% of the total variation and clearly separated the Great Australian Bight (area 1) and the Cascade Plateau/Tasman Rise (area 6) from the other areas (Fig. 4). No large fish were sampled from area 8. The third canonical axis, not shown, accounted for a further 11% of the variation and pulled area 7 to

one side separating it from the other areas at the 95% level of confidence but not at the 99% level. The parasite with the greatest discriminating power for the medium and large fish was the spirurid. These results show that five parasite faunas could be distinguished (at the 95% level), those of areas 1, 6, 7 and 8, all of which were different from each other and from areas 2, 3, 4 and 5 whose faunas were indistinguishable.

Plots of the New Zealand data indicated that the parasite fauna of fish from the three areas, Challenger Plateau (area 9), combined Cook and Moeraki Canyons (area 10), and the Chatham Rise (area 11) were distinct (Figs. 5, 6 and 7). Duplicate samples taken in the same month from areas 10 (10a and 10b) and 11 (11a and 11b) fell close together. The first two canonical axes accounted for 94%, 96% and 93% of the total variation respectively for small, medium and large size groups. The parasites with the greatest discriminating powers for these analyses were Anisakis type 3 for small fish, and the spirurid for the medium and large fish.

To determine whether significant parasitological differences occurred between fish from New Zealand and Australia, those from both countries were analysed together. Only the medium and large size fish were analysed in this way, because the 'small' size groups we used differed in average lengths between the two countries. Data from areas 2,3,4 and 5 were combined into a single sample for this analysis, as were the duplicate New Zealand samples from area 10 and area 11.

For the medium fish, the first two canonical axes took out 84% of the total variation and separated all areas from each

other at the 99% level of confidence except for the Cascade Plateau/Tasman Rise (area 6) and the Chatham Rise (area 11) which were not clearly distinguished, even when the third axis was taken into account. For the large fish, the first two canonical axes took out over 81% of the total variation and separated all areas at the 99% level of confidence except the combined Australian areas 2, 3, 4 and 5, and the Challenger Plateau (area 9) whose confidence rings overlapped. They were separate at the 95% level of confidence. The parasite with the most discriminating power for the medium and large fish was the spirurid. We concluded that there was no parasitological evidence that Australian and New Zealand roughy stocks mixed because the overlapping samples were not geographically contiguous and the results were inconsistent between the two size groups.

Orange roughy in southern Australian waters are believed to spawn from June to August (Evans and Wilson, 1987). We examined our parasite data to see whether we could detect any difference between fish taken near the spawning season and those taken in the same place well outside the spawning season. If a difference existed it would be evidence for a spawning migration. We had four pairs of samples where this could be tested. Analysis of the variance in the data showed few statistically significant differences between the pairs of samples with respect to individual parasites (Table 2) indicating that the parasite faunas of fish taken near the spawning season were similar to those taken outside the spawning season. We concluded that there was no parasitological evidence that spawning fish migrate in from other areas. A similar comparison for New Zealand fish was not

possible because all New Zealand samples were taken during the spawning season.

Though the multivariate analyses could not distinguish between individual areas in the South Australia/west Victoria/west Tasmania complex (areas 2, 3, 4 and 5), examination of the data of Anisakis spp. suggested that nevertheless there were consistent differences. All four Anisakis categories were more abundant in the more southerly fish. In Table 3 the four categories have been combined and the average log (x+1) of the total given for the four areas, reading from north to south, for the three fish size groups. An analysis of the correlation between latitude and transformed parasite number indicated a positive correlation for the small and medium sized fish at the 99% level of confidence, and no significant correlation for the large fish. As the small size category contained predominantly juvenile fish and the medium size category mature fish (length at first maturity 30 cm LCF for males and 33 cm LCF for females; Evans and Wilson, 1987), it appears that medium-sized mature fish do not move far from the area where they lived as juveniles. The cline is not evident in the large fish, possibly because of the small sample sizes.

Discussion

The use of parasites to identify stocks, that is population units for fisheries management purposes, relies on the assumption that spawning fish release eggs which repopulate the same area. Orange roughy eggs are less dense than sea water and rise in the water column (Pankhurst, McMillan and Tracey, 1987). Though they

appear to have low energy reserves the duration of their pelagic phase is unknown.

Multivariate analyses of the data from the 263 medium and the 260 large southern Australian fish discriminated more areas than analysis of data from the 279 small fish. This was evidently because more parasites were present in the medium and large fish than in the small fish. It illustrates a general rule concerning the use of parasites as population markers which is, that within a species the older the fish sampled the more likely it is to be parasitised and therefore the more chance there is of discriminating one stock from another.

One other study has made extensive use of canonical variate analysis in the interpretation of fish parasite abundance, that of Lester et al. (1985). They used data from skipjack tuna in the central and southwestern Pacific, and their results differ dramatically from those presented here. Using long-lived parasites they could not discriminate between skipjack samples taken 4000 km apart even at a 95% level of confidence. They concluded that extensive mixing occurred, as had been predicted by tagging studies (Kleiber and Kearney, 1983). The torpedo shape of a skipjack is consistent with high mobility; the blunt irregular head of a roughy suggests a more sedentary life style.

There was no evidence in the parasitological data that fish from one of our 5 identified Australian stocks moved into the area of another identified stock to spawn. As far as we could determine, fish caught during the spawning season had a similar parasite fauna to those caught in the same locality outside the spawning season. In New Zealand, the fishery is based on

spawning season aggregations possibly formed from fish that migrate in from other areas (Robertson et al., 1984). Whether or not this is so may be determined by comparing the parasite fauna of New Zealand spawning fish with that of fish taken from the same sites outside the spawning season.

In contrast to our parasitological findings, Smith (1986) found little genetic separation in samples of orange roughy from several sites in Australia and New Zealand. In some fisheries, parasitological and isoenzyme studies have lead to similar conclusions with regard to stock composition, such as the work by Lester et al.(1984) and Richardson (1983), where neither study was able to detect more than one stock of skipjack in the central and southwest Pacific. In other fisheries, the parasitological and isoenzyme findings have appeared to be at variance, as is the case here. MacKenzie (1983) using parasites concluded that there were at least two sources of recruitment for herring around Scotland, and that adult herring on the west coast comprised a small proportion of fish that were recruited locally and a large proportion that had come from the eastern North Sea. Grant (1982) using isoenzymes was not able to differentiate any European populations.

There are two reasons for apparent conflict in the conclusions from the two methods. First, parasite data relate to differences in the history of individual fish; genetic studies detect changes over an evolutionary time scale. Recently isolated fish populations may not have developed sufficient differences for them to be distinguished genetically though they may have different parasite faunas. The short time scale to which parasite data relates is similar to that of tag data except

that the parasite fauna reflects the environment of the fish up to the time it is caught whereas tag data relates to the history of the fish only for the time between tagging and recapture. A combination of parasite and tag data is a powerful tool in evaluating the movement of fish, see for example the work on whiting by Hislop and MacKenzie (1976).

Second, a small amount of gene flow will make it difficult to recognise semi-isolated stocks. Certainly the movement of only a few fish were considered by Grant (1982) sufficient to obscure any differences that might have been present in European herring. The high genetic diversity in orange roughy found by Smith (1986) may be caused by low rates of gene exchange between partly isolated populations. This is consistent with the relatively sedentary mode of life for this fish that we propose.

Acknowledgments. We thank the New Zealand Fisheries Research Division and the Fisheries Division, New South Wales, for fish samples, and Dr. I. Beveridge, South Australian Department of Agriculture, and Dr. R.A. Bray, British Museum (Natural History), for taxonomic help. Dr. G.N. Berry, Dr. T.H. Cribb, Ms. J.M. Masel and Mr G.A. West helped with dissections. Dr F.R. Harden Jones, CSIRO Fisheries Division, kindly commented on an earlier draft of the manuscript. The project was funded by a grant from the Fishing Industry Research Trust Account (FIRTA 84/27).

Table 3. Average $\log(x+1)$ number of Anisakis spp. in H. atlanticus of three length groups from four areas. Data from small fish adjusted to a fish of length 28 cm, those from medium fish to 37 cm, and those from large to 42 cm. Sample sizes are given in parentheses.

	Latitude	Small	Medium	Large
Area 2	37.9°S	1.22 (87)	2.40 (34)	3.92 (10)
Area 3	40.5°S	1.32 (13)	2.77 (15)	3.59 (18)
Area 4	41.6°S	1.69 (26)	3.06 (32)	3.85 (35)
Area 5	42.2°S	1.97 (12)	2.86 (20)	3.84 (15)

Figure captions

Fig. 1. Origins of the eleven samples of Hoplostethus atlanticus from Australia and New Zealand, and the 1000 m isobath.

Fig. 2. Results of multivariate analysis on small fish from southern Australia using 8 parasites (no.s 2, 3+4, and 7 to 12) from 8 areas indicated in Fig. 1. 99% confidence rings given for samples of more than 10 fish.

Fig. 3. Results of multivariate analysis on medium fish from southern Australia using 8 parasites (no.s 2, 3+4, and 7 to 12) from 8 areas indicated in Fig. 1. 99% confidence rings given for samples of more than 10 fish.

Fig. 4. Results of multivariate analysis on large fish from southern Australia using 8 parasites (no.s 2, 3+4, and 7 to 12) from 7 areas indicated in Fig. 1. 99% confidence rings given for samples of more than 10 fish.

Fig. 5. Results of multivariate analysis on small fish from New Zealand using 8 parasites (no.s 2, 3+4, and 7 to 12) from 3 areas indicated in Fig. 1 with 99% confidence rings.

Fig. 6. Results of multivariate analysis on medium fish from New Zealand using 8 parasites (no.s 2, 3+4, and 7 to 12) from 3 areas indicated in Fig. 1 with 99% confidence rings.

Fig. 7. Results of multivariate analysis on large fish from New Zealand using 8 parasites (no.s 2, 3+4, and 7 to 12) from 3 areas indicated in Fig. 1 with 99% confidence rings.
